## Abstract

Experiments on brain samples under multiaxial loading have shown that human brain tissue is both extremely soft when compared to other biological tissues and characterized by a peculiar elastic response under combined shear and compression/tension: there is a significant increase in shear stress with increasing axial compression compared to a moderate increase with increasing axial tension. Recent studies have revealed that many widely used constitutive models for soft biological tissues fail to capture this characteristic response. Here, guided by experiments of human brain tissue, we develop a family of modeling approaches that capture the elasticity of brain tissue under varying simple shear superposed on varying axial stretch by exploiting

## 1. Introduction

The study of the mechanical response of biological systems within a continuum framework relies on constitutive equations relating stresses to strains [17]. In the absence of a method to derive these constitutive equations from first principles, phenomenological models are routinely used. In particular, when a system behaves in the elastic regime, classes of hyperelastic models have been proposed for many tissues and organs. Ideally, these models are systematically calibrated and validated on multiaxial loading data [28, 45]. Rather than using brute force and fit data to arbitrary strain-energy functions, it is well understood that a key element of constitutive modeling is to consider families of models with desirable properties. For instance, collagen-rich soft tissues are known to be mostly incompressible and display strong strain-stiffening response. Therefore, most of the current models for these tissues start with a functional form that both enforces these particular properties and is general enough to be adapted for specific systems.

Brain tissue is strikingly different from most soft biological tissues: its microstructure is not governed by collagen and elastin fibers, which implies that brain typically lacks the characteristic strain-stiffening behavior of arteries, skeletal and cardiac muscle, or skin [14, 15]. The typical behavior of these tissues, captured by models such as Fung's or Gent's [18], is that a strong stiffening is obtained at finite extension leading either to a singular limit (in the case of the Gent model) or exponential behavior (for the Fung model). Data analyses shows that these models are not suitable for brain tissue [23]. A natural problem is then to understand the defining characteristics of brain tissue and to identify a suitable family of hyperelastic models with these characteristics. Moreover, a model for brain tissue needs to be suitable for small to moderate strain as experienced in vivo [1].

The analysis presented in this paper is based on the data of human brain tissues tested under finite uniaxial and multiaxial loading reported in [4]. In this article,

the authors have established that the microstructural anisotropy due to the alignment of nerve fibers in the tissue does not result in an anisotropic elastic response similar to the effect of collagen fibers in other soft tissues. Therefore, we neglect a possible anisotropic response and assume here that brain tissue is isotropic. Another important consideration is the viscoelastic response of brain tissue. The data shows clearly that the response of brain tissue has a viscous component indicated by a different response in loading and unloading. However, in the first instance, we are interested in the tissue’s effective elastic response under small strain rate. Following [4], this response is obtained as the average between the loading and the unloading paths, assuming that this corresponds to the case when the strain rate approaches zero and the hysteresis vanishes. Therefore, for the rest of our analysis, we restrict our attention to isotropic elastic models.

In the elastic regime, recent experiments on brain tissues have further established another response under combined compression and shear, namely that the elastic shear stress increases sharply with increasing axial compression, while it only increases moderately with increasing tension [4, 21, 35, 23]. From a modeling point of view, capturing this apparently contradictory behavior represents a major challenge. Similar behaviors were also observed in other soft tissues with large lipid content, such as adipose tissue [23].

For brain and adipose tissues, Ogden-type hyperelastic incompressible isotropic models [32] have been found in good agreement with the experimental data, both in single and multiaxial loading [4, 7, 9, 12, 23, 26, 27, 30, 31, 37, 39, 40, 41], and the relative errors from their nonlinear least-squares fit to the experimental data suggest that the models with higher order terms are more successful in approximating the data than the ones with lower order terms. However, even though Ogden-type constitutive models are widely appealing since they are readily implemented in many popular software packages, the fact that a relatively large number of parameters may be required to approximate the data to the desired accuracy makes them less attractive to users.

Here, our objective is to build a family of isotropic hyperelastic strain-energy functions, with a small number of parameters, that exhibit the characteristic behavior under combined shear and compression or tension. To achieve this, we devise a systematic strategy to derive such models and demonstrate their performance on experimental data for human brain tissue from [4]. Our algorithmic approach is generic and, as such, applicable to other biological tissues with similar properties, including adipose tissue. We start our analysis in Section 2, with a detailed study of the deformation of a cuboid of isotropic hyperelastic material under simple shear superposed on finite axial stretch. This analysis reveals the crucial role of the nonlinear shear

modulus defined as the ratio between the shear stress and the shear strain. Unlike the linear shear modulus which is a constant, in general, the nonlinear shear modulus is a function of the deformation that enables us to identify characteristic behaviors under large shear superposed on large compression or tension. In Section 3, we show that, for a given shear superposed on finite compression or tension, the elastic behavior under large shear is consistent with that under small shear. This observation is used to identify a generic strain-energy function capable of predicting the physical behavior of human brain tissues subjected to combined shear and tension or compression. In Sections 4 and 5, we exploit our key observations from the experimental data and employ the nonlinear shear modulus to derive a family of hyperelastic models with a small number of parameters that predict the elastic behavior of brain tissue under combined shear and axial loading and are suitable for finite-element analyses.

## 2. Finite shear superposed on axial stretch

The finite elastic deformation of a material body is described by the mapping  $\mathbf{x} = \boldsymbol{\chi}(\mathbf{X})$ , which defines a one-to-one correspondence between the positions of material points in the reference configuration  $\mathbf{X} = (X, Y, Z) \in \mathcal{B}_0$  and their positions in the current configuration  $\mathbf{x} = (x, y, z) \in \mathcal{B}$ . Kinematics quantities for the deformation [2, 46] are associated with the deformation gradient

$$\mathbf{F} = \text{Grad } \boldsymbol{\chi}. \quad (1)$$

Here, we restrict our attention to hyperelastic isotropic materials. These materials are described by a strain-energy function  $\mathcal{W}(\lambda_1, \lambda_2, \lambda_3)$ , where  $\{\lambda_i\}_{i=1,2,3}$  are the principal stretches [33, p. 94]. We assume that the material is incompressible so that  $J = \det \mathbf{F} = \lambda_1 \lambda_2 \lambda_3 = 1$ . Then, the Cauchy stress tensor has the representation:

$$\boldsymbol{\sigma} = -p\mathbf{I} + \beta_1\mathbf{B} + \beta_{-1}\mathbf{B}^{-1}, \quad (2)$$

where  $\mathbf{I}$  is the identity tensor,  $\mathbf{B} = \mathbf{F} \cdot \mathbf{F}^T$  is the left Cauchy-Green tensor,  $p$  is the Lagrange multiplier associated with the incompressibility constraint  $J = 1$ , and

$$\begin{aligned} \beta_1 &= \frac{1}{\lambda_1^2 - \lambda_2^2} \left( \frac{\lambda_1^2 + \lambda_3^2}{\lambda_1} \frac{\partial \mathcal{W}}{\partial \lambda_1} - \frac{\lambda_2^2 + \lambda_3^2}{\lambda_2} \frac{\partial \mathcal{W}}{\partial \lambda_2} \right), \\ \beta_{-1} &= \frac{1}{\lambda_1^2 - \lambda_2^2} \left( \frac{1}{\lambda_1} \frac{\partial \mathcal{W}}{\partial \lambda_1} - \frac{1}{\lambda_2} \frac{\partial \mathcal{W}}{\partial \lambda_2} \right), \end{aligned} \quad (3)$$

are the constitutive coefficients.

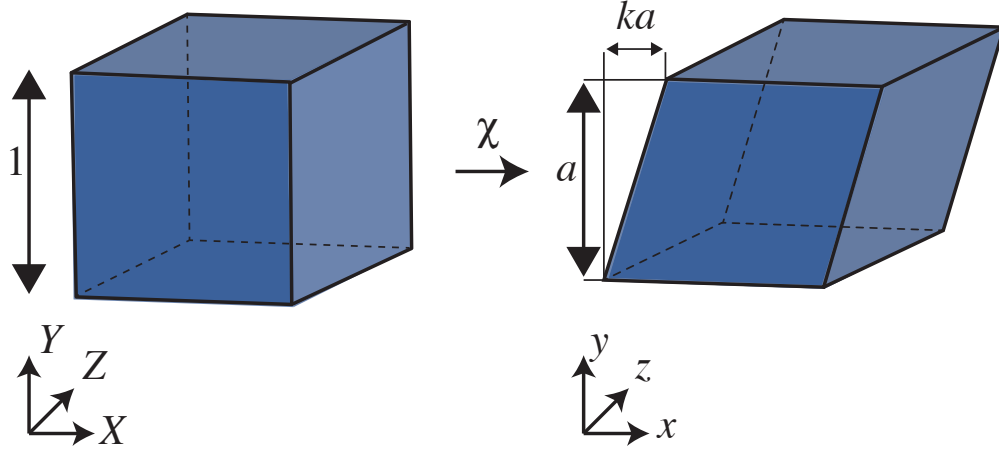

Figure 1: Cuboid (left) deformed by simple shear superposed on axial stretch (right).

We consider an elastic cuboid deformed by simple shear superposed on axial stretch. This idealized deformation has been first proposed by Rajagopal and Wine-  
man [38] and used both to study the Poynting effect and to fit experimental data [4, 10, 23, 24, 25]. In Cartesian coordinates, it reads

$$x = \frac{X}{\sqrt{a}} + kaY, \quad y = aY, \quad z = \frac{Z}{\sqrt{a}}, \quad (4)$$

where  $(X, Y, Z)$  and  $(x, y, z)$  are the coordinates of the reference and current configurations, respectively (see Figure 1). The deformation gradient for this deformation is

$$[\mathbf{F}] = \begin{bmatrix} 1/\sqrt{a} & ka & 0 \\ 0 & a & 0 \\ 0 & 0 & 1/\sqrt{a} \end{bmatrix}, \quad (5)$$

where  $a > 0$  is the (constant) *axial stretch*,  $(a - 1)$  is the *axial strain*,  $k > 0$  is the *shear parameter*, and  $ka > 0$  is the *shear strain*.

The corresponding left Cauchy-Green deformation tensor takes the form

$$[\mathbf{B}] = \begin{bmatrix} 1/a + k^2 a^2 & ka^2 & 0 \\ ka^2 & a^2 & 0 \\ 0 & 0 & 1/a \end{bmatrix}, \quad (6)$$

with the eigenvalues

$$\begin{aligned}\lambda_1^2 &= \frac{1 + a^3(1 + k^2) + \sqrt{[1 + a^3(1 + k^2)]^2 - 4a^3}}{2a} = \lambda^2, \\ \lambda_2^2 &= \frac{1 + a^3(1 + k^2) - \sqrt{[1 + a^3(1 + k^2)]^2 - 4a^3}}{2a} = a\lambda^{-2}, \\ \lambda_3^2 &= \frac{1}{a}.\end{aligned}\tag{7}$$

The principal invariants of the tensor  $\mathbf{B}$  in (6) are

$$\begin{aligned}I_1 &= \text{tr}(\mathbf{B}) = a^2(1 + k^2) + \frac{2}{a} = \lambda_1^2 + \lambda_2^2 + \lambda_3^2, \\ I_2 &= \frac{1}{2}[(\text{tr} \mathbf{B})^2 - \text{tr}(\mathbf{B}^2)] = a(2 + k^2) + \frac{1}{a^2} = \lambda_1^2\lambda_2^2 + \lambda_2^2\lambda_3^2 + \lambda_3^2\lambda_1^2, \\ I_3 &= \det \mathbf{B} = 1 = \lambda_1^2\lambda_2^2\lambda_3^2.\end{aligned}\tag{8}$$

We note that we can rewrite the second invariant as  $I_2 = \lambda_1^{-2} + \lambda_2^{-2} + \lambda_3^{-2}$ . The non-zero components of the associated Cauchy stress (2) are

$$\begin{aligned}\sigma_{xx} &= \sigma_{zz} + \beta_1 k^2 a^2, \\ \sigma_{yy} &= \sigma_{zz} + \left(a^2 - \frac{1}{a}\right) \left(\beta_1 - \frac{\beta_{-1}}{a}\right) + \beta_{-1} k^2 a, \\ \sigma_{zz} &= -p + \frac{\beta_1}{a} + a\beta_{-1}, \\ \sigma_{xy} &= ka^2 \left(\beta_1 - \frac{\beta_{-1}}{a}\right),\end{aligned}\tag{9}$$

and the principal stresses are given by [46, p. 143]

$$\sigma_i = \lambda_i \frac{\partial \mathcal{W}}{\partial \lambda_i} - p, \quad i = 1, 2, 3.\tag{10}$$

A convenient way to quantify the shear response of a material under shear stress is to introduce the following *nonlinear shear modulus* [46, p. 174-175]

$$\mu = \frac{\sigma_1 - \sigma_2}{\lambda_1^2 - \lambda_2^2} = \frac{1}{\lambda_1^2 - \lambda_2^2} \left( \lambda_1 \frac{\partial \mathcal{W}}{\partial \lambda_1} - \lambda_2 \frac{\partial \mathcal{W}}{\partial \lambda_2} \right).\tag{11}$$

This modulus is a function of the deformation. In our case, it can be parametrized in terms of the axial stretch  $a$  and the shear parameter  $k$  as  $\mu = \mu(a, k)$ . Equivalently,

the nonlinear shear modulus can be written in terms of the constitutive coefficients, using (3), as

$$\mu(a, k) = \beta_1 - \frac{\beta_{-1}}{a}. \quad (12)$$

It is easier in experiments to measure the components of the first Piola-Kirchhoff stress defined as the force per unit area in the reference configuration [46, pp. 124-125]

$$\mathbf{P} = (\det \mathbf{F}) \boldsymbol{\sigma} \cdot \mathbf{F}^{-\top}. \quad (13)$$

Since the shear component of the first Piola-Kirchhoff stress tensor  $P_{xy} = \sigma_{xy} a$  is proportional to the shear strain  $ka$ , the *nonlinear shear modulus* (11), or equivalently (12), is simply the ratio between the elastic shear stress  $P_{xy}$  and the shear strain  $ka$ , i.e.,

$$\mu(a, k) = \frac{\sigma_{xy}}{ka^2} = \frac{P_{xy}}{ka}. \quad (14)$$

Hence the nonlinear shear modulus defined here can be obtained directly from the experimental measurements.

There are two interesting limits of the nonlinear shear modulus. First, when the axial stretch  $a$  is finite and the shear strain is small, i.e., for infinitesimal simple shear superposed on finite axial stretch, the nonlinear shear modulus (11) converges to

$$\tilde{\mu}(a) = \lim_{k \rightarrow 0} \mu(a, k). \quad (15)$$

Second, in the linear elastic limit, the nonlinear shear modulus (11) converges to the well-known linear shear modulus  $\mu_0$  of the infinitesimal theory,

$$\mu_0 = \lim_{a \rightarrow 1} \left( \lim_{k \rightarrow 0} \mu(a, k) \right) = \lim_{a \rightarrow 1} \tilde{\mu}(a). \quad (16)$$

### 3. Modeling strategy

Our objective is to identify a strain-energy function that can predict the physical behavior of human brain tissues subjected to combined shear and tension or compression. The experimental setup is described in detail in [4] and summarized in Appendix A, and the deformation attained is idealised by the homogeneous deformation (4). Note that obtaining ideal homogeneous deformations with very soft samples is known to be challenging as ideal frictionless boundary conditions are difficult to achieve and barreling may occur in compression. However, it remains our main theoretical tool in an attempt to organise the data. Accordingly, for a fixed axial stretch  $a$  and shear parameter  $k$ , we measure the shear component  $P_{xy}$  of the

first Piola-Kirchhoff stress tensor and calculate the corresponding nonlinear shear modulus  $\mu$  using equation (14).

Figure 2 summarizes the nonlinear shear modulus  $\mu(a, k)$  extracted from the experimental data for human brain tissue tested under multiaxial loading conditions [4] (see Appendix A). Two interesting characteristics emerge from these figures. First, in Figure 2A, we observe that the variation of the nonlinear shear modulus with respect to the shear parameter is similar for different values of fixed stretches, up to global vertical shift. Indeed, the different curves have the same qualitative characteristics shape. Second, in Figure 2B, we observe that, under large compressive loading, the nonlinear shear modulus increases sharply and almost linearly as the stretch parameter  $0 < a < 1$  decreases, while under tension, the nonlinear shear modulus remains almost constant or increases moderately as the parameter  $a > 1$  increases. Strikingly, although this behavior was observed before for small shear [21, 23, 35], here we see that the behavior of the nonlinear shear modulus with respect to the stretch at finite fixed shear is similar to that under small shear.

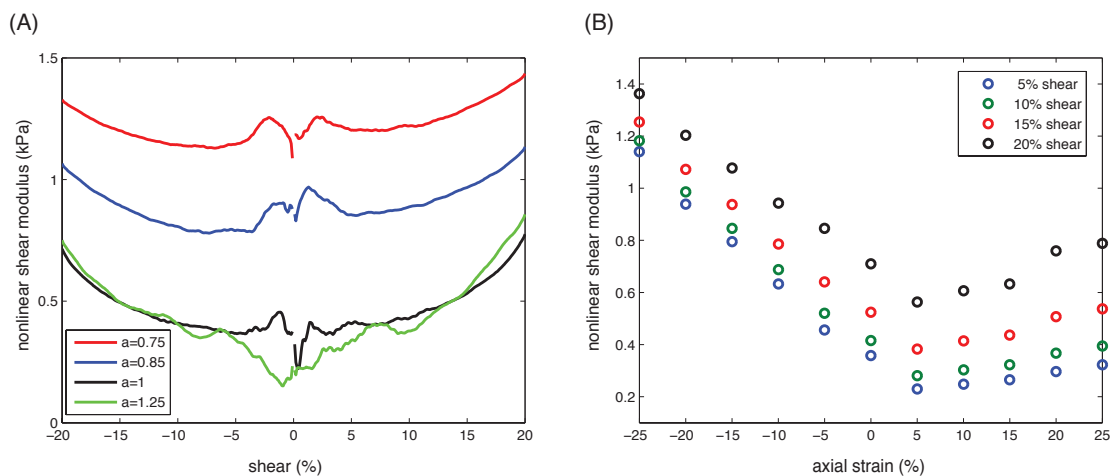

Figure 2: Nonlinear shear modulus given by the experimental measurements for brain tissue (A) under simple shear superposed on axial tension or compression, and (B) under varying compression and tension levels evaluated at different levels of shear. As the experiments suggest, the nonlinear shear modulus at any fixed shear increases significantly with increasing compression and remains almost constant or increases moderately with increasing tension. Here and in all the following figures the axial strain is  $(a - 1)$ .

### 3.1. Preliminary considerations

Our modeling strategy can accommodate various forms of strain-energy functions. Here, we consider the following Ogden-type model [32], which will be useful in predicting the characteristic elastic behavior under simple shear superposed on finite axial stretch,

$$\mathcal{W}_{\text{og}}(\lambda_1, \lambda_2, \lambda_3) = \frac{c_0(a)}{2\alpha(a)} \left( \lambda_1^{2\alpha(a)} + \lambda_2^{2\alpha(a)} + \lambda_3^{2\alpha(a)} - 3 \right). \quad (17)$$

We know from [4] and [23] that Ogden models can capture the qualitative trend reported above. Indeed, for each prescribed stretch  $a$ , the particular model (17) captures our experimental data well if  $c_0(a)$  and  $\alpha(a)$  change with the stretch parameter  $a$  [4] (see Appendix B). For fixed  $a$ , the corresponding principal stresses take on the form

$$\sigma_i = c_0(a)\lambda_i^{2\alpha(a)} - p, \quad i = 1, 2, 3. \quad (18)$$

Then the nonlinear shear modulus (11) simplifies to

$$\mu(a, k) = c_0(a) \frac{\lambda_1^{2\alpha(a)} - \lambda_2^{2\alpha(a)}}{\lambda_1^2 - \lambda_2^2}. \quad (19)$$

When the shear strain is small, the nonlinear shear modulus (23) converges to

$$\tilde{\mu}(a) = \lim_{k \rightarrow 0} \mu(a, k) = c_0(a) \frac{a^{1-\alpha(a)}(1 - a^{3\alpha(a)})}{1 - a^3}. \quad (20)$$

In the linear elastic limit, this modulus becomes

$$\mu_0 = \lim_{a \rightarrow 1} \tilde{\mu}(a) = c_0(1)\alpha(1). \quad (21)$$

However, a constitutive model of the form (17) fails to simultaneously capture the constitutive response of brain tissue at different stretch levels when using the calibration approach tested in [4] (see Appendix B). This suggests that either a different calibration strategy is required or a different constitutive model should be considered. We consider both approaches next. First, we develop a different calibration strategy. Second, we consider constitutive models with more parameters.

## 4. One-term (two-parameter) constitutive model

As shown in Figure 2, for a given shear superposed on varying levels of tension and compression, the changes in the nonlinear shear modulus under large shear computed

from the experimental data are consistent with those under small shear. In particular, this modulus increase sharply in compression as  $0 < a < 1$  decreases, and remains almost constant or increase moderately in tension as  $a > 1$  increases. Theoretically, we notice that, since in (17), the parameters  $c_0(a)$  and  $\alpha(a)$  depend only on the stretch  $a$ , constant values for these parameters can be obtained by calibrating to the corresponding experimental results the nonlinear shear modulus for small shear superposed on varying axial stretches  $a$  (20). Once the model parameters are found, they can be used to predict the nonlinear shear modulus (19), and hence the elastic behavior under large shear superposed on different axial deformations.

To obtain a hyperelastic model that captures the observed behavior of human brain tissue while keeping the number of model parameters low, we consider the one-term (two-parameter) Ogden model (17) with the strain-energy function

$$\mathcal{W}_0(\lambda_1, \lambda_2, \lambda_3) = \frac{c_0}{2\alpha} (\lambda_1^{2\alpha} + \lambda_2^{2\alpha} + \lambda_3^{2\alpha} - 3), \quad (22)$$

where  $c_0$  and  $\alpha$  are constant parameters independent of the stretch value  $a$ . These model parameters can be found from the experimental data of human brain tissue under small shear superposed on varying axial stretches  $a$ , as in [23]. Then the constitutive model (22) can be deformed by finite simple shear or by simple shear superposed on any finite axial stretch (4) with the shear parameter  $k$  and axial stretch  $a$ . In this case,  $c_0$  and  $\alpha$  are fixed material parameters, and the nonlinear shear modulus (19), the nonlinear shear modulus under small shear strain (20), and their linear elastic limit (21) take on the following explicit forms:

$$\mu(a, k) = c_0 \frac{\lambda_1^{2\alpha} - \lambda_2^{2\alpha}}{\lambda_1^2 - \lambda_2^2}, \quad (23)$$

$$\tilde{\mu}(a) = \lim_{k \rightarrow 0} \mu(a, k) = c_0 \frac{a^{1-\alpha} (1 - a^{3\alpha})}{1 - a^3}, \quad (24)$$

$$\mu_0 = \lim_{a \rightarrow 1} \tilde{\mu}(a) = c_0 \alpha. \quad (25)$$

#### 4.1. Model calibration

In this section, we devise a two-step procedure to calibrate the strain-energy function (22) to the human brain experiments. The only experimental measurements that we require for the model calibration correspond to the nonlinear shear modulus for small shear superposed on varying axial deformations. To calibrate the constant parameters to the experimental data, we employ a nonlinear least squares procedure in Matlab, `lsqnonlin.m` [4, 23, 34]. We then compare the predicted results with experimental data for finite simple shear superposed on axial tension or compression.

*Step 1.* (preliminary approximation of experimental data) First, we consider the experimental data for simple shear, up to 20%, and for simple shear superposed on any fixed axial stretch, up to 25% tension or compression (in 5% increments), and note that the available data are highly reliable at more than 5% shear, but contain some noise in the low shear range, at less than 5% in magnitude. To identify more reliable values everywhere, we calibrate the strain-energy function  $\mathcal{W}_{\text{og}}$  of equation (17) to the experimental data for fixed axial stretch and finite simple shear by varying the parameters  $c_0(a)$  and  $\alpha(a)$  with the stretch parameter  $a$ . We can calibrate this model using the experimental data of human brain tissue for shear stress under simple shear superposed on a fixed axial stretch.

In Appendix B, we summarize the constitutive behavior of the calibrated model, which shows excellent agreement with the experimental results at more than 5% shear and offers reliable predictions of the elastic behavior at less than 5% shear. In particular, for each axial stretch  $a$ , the nonlinear shear modulus under small shear  $\tilde{\mu}(a)$  is given by (20) and the predicted values are denoted by  $\tilde{\mu}_{\text{data}}(a)$ . In the linear elastic limit, the shear modulus (21) is equal to  $\mu_0 = 0.3379$  kPa.

*Step 2.* (constitutive model calibration) Second, in order to accurately capture the behavior of the nonlinear shear modulus at different values of the axial stretch, we consider the hyperelastic model characterized by the strain-energy function  $\mathcal{W}_0$  of equation (22). For this model, we calibrate the nonlinear shear modulus  $\tilde{\mu}(a)$  of equation (24) for small shear superposed on varying axial deformations, up to 25% tension or compression (in 5% increments), to the corresponding values identified from the experimental data at Step 1,  $\tilde{\mu}_{\text{data}}(a)$ , and obtain the constant parameters  $c_0 = -0.0939$  kPa and  $\alpha = -4.0250$ . This calibration is illustrated in Figure 3 together with the associated relative error  $|P_{xy}^{\text{model}} - P_{xy}^{\text{data}}|/|P_{xy}^{\text{data}}|$ , where  $P_{xy}^{\text{model}}$  and  $P_{xy}^{\text{data}}$  are the predicted and measured values of the shear stress, respectively, and  $|\cdot|$  denotes the absolute value.

According to equation (25), the calibrated model predicts a linear shear modulus of  $\mu_0 = c_0\alpha = 0.3779$  kPa and a Young's modulus of  $E_0 = 3\mu_0 = 1.1338$  kPa, i.e., this model offers a very good approximation in the linear elastic regime, where a linear shear modulus  $\mu_0 = 0.3379$  kPa was identified from the experimental data at Step 1 (see Appendix B). This is to be expected, since the model was calibrated to data for small shear deformations (Figure 3). For comparison, a similar one-term (two-parameter) Ogden strain-energy function but a different calibration method, was used in [4], and a shear modulus of  $\mu_0 = 0.66$  kPa was found, but it was also noted that this value overestimates the stiffness under the linear elastic regime.

Table 1 summarizes the strain-energy function for the proposed model, its constant parameters, their calibrated values, and units. Figure 4 shows the predicted

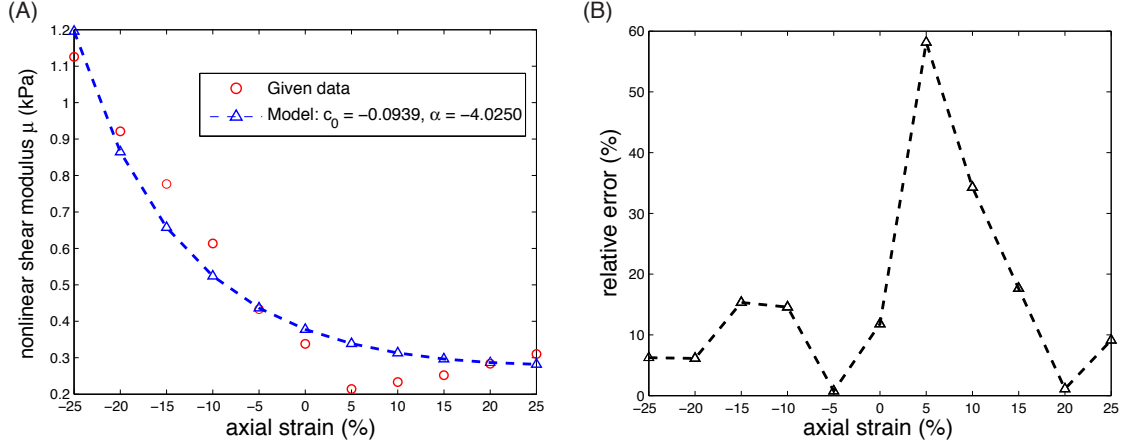

Figure 3: Constitutive behavior of strain-energy function  $\mathcal{W}_0 = c_0 (\lambda_1^{2\alpha} + \lambda_2^{2\alpha} + \lambda_3^{2\alpha} - 3) / (2\alpha)$  with parameters  $c_0 = -0.0939$  kPa and  $\alpha = -4.0250$  under small shear superposed on varying axial tension or compression: (A) nonlinear shear modulus  $\tilde{\mu}$  versus axial strain, given data and model, and (B) associated relative error for the shear stress  $P_{xy}$ .

Table 1: Strain-energy function with related model parameters and calibrated values (and units) for human brain tissues.

strain-energy function	eq.	model	parameter	value	unit
$\mathcal{W}_0$	(22)	Ogden	$c_0$	-0.0939	kPa
			$\alpha$	-4.0250	—
linear elastic limit	(25)	—	$\mu_0$	0.3779	kPa

shear stress  $P_{xy}$  and nonlinear shear modulus  $\mu$  compared to the experimental data for simple shear, up to 20% shear strain, superposed on up to 25% compression or tension (in 5% increments), and the relative errors.

**Remark 1.** *In the above calibration procedure, the preliminary Step 1, where reliable data for the nonlinear shear modulus under small shear deformations are identified, is performed only because the given experimental data are noisy in the small shear range, and more reliable values are required for the model calibration at Step 2. If reliable experimental data for the small shear deformations were provided directly, then Step 1 would not be necessary. At Step 2, the choice of the strain-energy function  $\mathcal{W}_0$  is not restricted to the particular form suggested here, but our present choice was guided by the fact that we wanted to keep the number of constant model parameters low. Moreover, although the approximation under small shear superposed on varying axial stretch in Figure 3 can be improved, as shown in Appendix C, under large shear deformations, the results remain similar. This is due to the fact that, as shown in Figure 2B, if compression increases, then the nonlinear elastic modulus increases slower under larger shear, but if tension increases, then the rate of increase in this modulus remains virtually the same for different levels of shear.*

## 5. Three-term (four-parameter) constitutive model

In this section, we construct a strain-energy function that matches the observed behaviors of human brain tissue under simple shear superposed on finite axial stretch by combining the Mooney-Rivlin model [29, 42]

$$\mathcal{W}_{\text{mr}}(\lambda_1, \lambda_2, \lambda_3) = \frac{c_1}{2} (\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) + \frac{c_2}{2} (\lambda_1^{-2} + \lambda_2^{-2} + \lambda_3^{-2} - 3), \quad (26)$$

where  $c_1$  and  $c_2$  are two constant parameters, with the one-term Ogden model (17). The Mooney-Rivlin model has the property that its nonlinear shear modulus depends only on  $a$ , i.e.,

$$\mu(a, k) = \tilde{\mu}(a) = c_1 + \frac{c_2}{a}. \quad (27)$$

Moreover, for this model, suitable values for the constant parameters can be found such that the nonlinear shear modulus increases linearly as the stretch parameter  $0 < a < 1$  decreases, and remains almost constant as the parameter  $a > 1$  increases, as shown in [23]. These particular characteristics of the Mooney-Rivlin model will be useful when approximating the stress-strain curves in Figure 2A, which are only translated vertically while their shape appears is almost invariant under variations of the stretch values  $a$ . To construct the strain-energy function for the constitutive model, we devise the following three-step procedure:

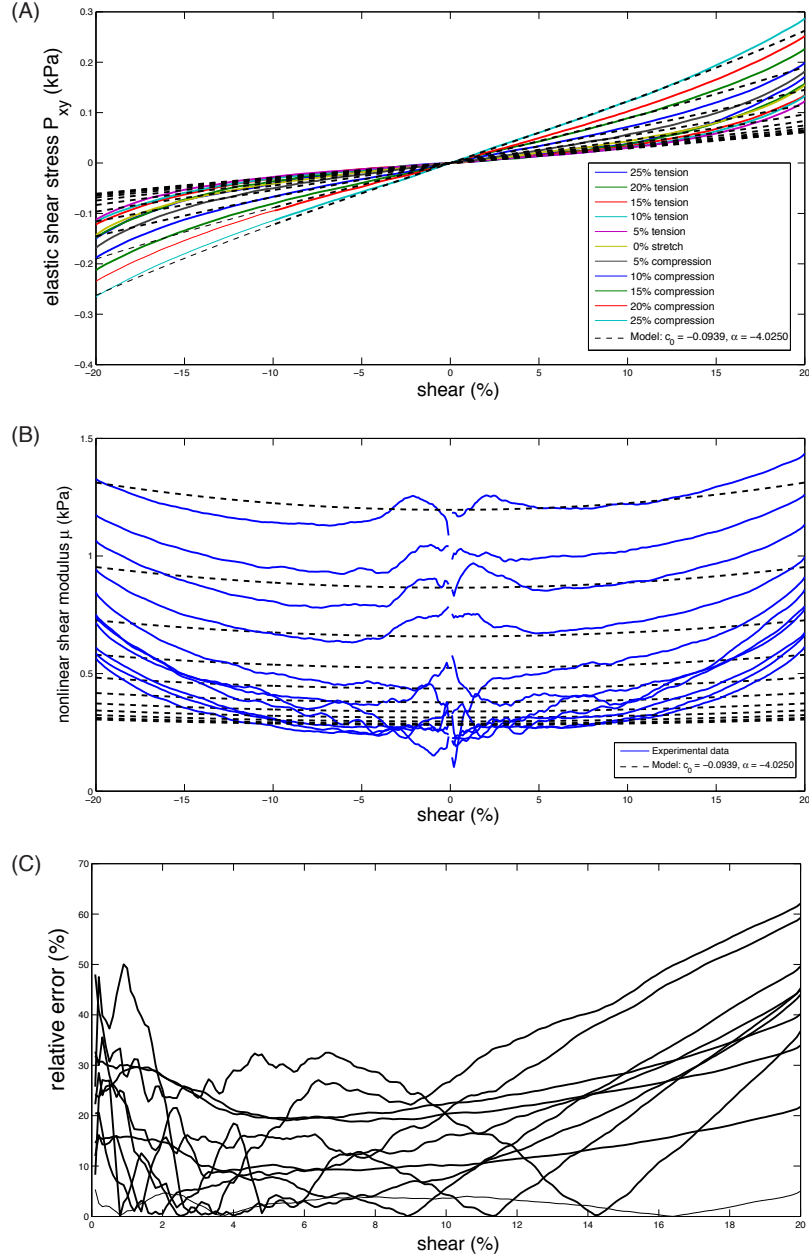

Figure 4: Constitutive behavior of strain-energy function  $\mathcal{W}_0 = c_0 (\lambda_1^{2\alpha} + \lambda_2^{2\alpha} + \lambda_3^{2\alpha} - 3) / (2\alpha)$  with parameters  $c_0 = -0.0939$  kPa and  $\alpha = -4.0250$  under simple shear superposed on different levels of axial tension or compression: (A) Shear stress  $P_{xy}$  versus shear strain, experiment and model, (B) nonlinear shear modulus  $\mu$  versus axial strain, experiment and model, and (C) associated relative error for the shear stress  $P_{xy}$ . The corresponding linear shear modulus is  $\mu_0 = 0.3779$  kPa.

*Step 1.* We begin with a three-term (four-parameter) Ogden model by additively combining the strain-energy functions (17) and (26),

$$\begin{aligned} \mathcal{W}_1(\lambda_1, \lambda_2, \lambda_3) = & \frac{c_0}{2\alpha} (\lambda_1^{2\alpha} + \lambda_2^{2\alpha} + \lambda_3^{2\alpha} - 3) \\ & + \frac{c_1}{2} (\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) + \frac{c_2}{2} (\lambda_1^{-2} + \lambda_2^{-2} + \lambda_3^{-2} - 3), \end{aligned} \quad (28)$$

where  $c_0$ ,  $\alpha$ ,  $c_1$ , and  $c_2$  are constant material parameters. To calibrate this model, we use the experimental data of human brain tissue for shear stress under simple shear superposed on a fixed axial stretch, as in [4], i.e., by fixing  $a$  in the deformation gradient (5). Then the constitutive model (28) can be deformed by simple shear or by simple shear superposed on any axial stretch (4) with the shear parameter  $k$  and axial stretch  $a$ . Since  $c_0$ ,  $\alpha$ ,  $c_1$ , and  $c_2$  are fixed material parameters, the nonlinear shear modulus (11) and the nonlinear shear modulus under small shear strain (15) take on the following explicit forms

$$\mu_1(a, k) = c_0 \frac{\lambda_1^{2\alpha} - \lambda_2^{2\alpha}}{\lambda_1^2 - \lambda_2^2} + c_1 + \frac{c_2}{a}, \quad (29)$$

$$\tilde{\mu}_1(a) = \lim_{k \rightarrow 0} \mu_1(a, k) = c_0 \frac{a^{1-\alpha} (1 - a^{3\alpha})}{1 - a^3} + c_1 + \frac{c_2}{a}. \quad (30)$$

*Step 2.* Next, in order to approximate the nonlinear shear modulus at different values of the axial stretch while preserving the changes with shear from the previous step (as shown in Figure 2A), we augment the strain-energy function  $\mathcal{W}_1$  of (28) by a correction function  $\mathcal{W}_2$  to obtain an isotropic hyperelastic model of the form

$$\mathcal{W}(\lambda_1, \lambda_2, \lambda_3) = \mathcal{W}_1(\lambda_1, \lambda_2, \lambda_3) + \mathcal{W}_2(\lambda_1, \lambda_2, \lambda_3). \quad (31)$$

For the hyperelastic model (31), the nonlinear shear modulus (11) is simply the sum of the nonlinear shear moduli of both functions, i.e.,

$$\mu = \frac{1}{\lambda_1^2 - \lambda_2^2} \left( \lambda_1 \frac{\partial \mathcal{W}}{\partial \lambda_1} - \lambda_2 \frac{\partial \mathcal{W}}{\partial \lambda_2} \right) = \mu_1 + \mu_2. \quad (32)$$

where  $\mu_1$  is the nonlinear shear modulus (29) of the strain-energy function  $\mathcal{W}_1$ , given by (28), and  $\mu_2$  is the nonlinear shear modulus of the correction function  $\mathcal{W}_2$  which needs to be determined. Motivated by our experimental observations, the nonlinear shear modulus  $\mu$  given by (32) must increase sharply in compression as  $0 < a < 1$  decreases, and remain almost constant or increase moderately in tension as  $a > 1$  increases (see Figure 2). To satisfy these conditions, we look for a nonlinear

shear modulus correction  $\mu_2(a, k) = \tilde{\mu}_2(a)$ , varying only with the stretch parameter  $a$ . Since the Mooney-Rivlin model is the only prominent model that satisfies this condition, we consider

$$\mathcal{W}_2(\lambda_1, \lambda_2, \lambda_3) = \frac{b_1}{2} (\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) + \frac{b_2}{2} (\lambda_1^{-2} + \lambda_2^{-2} + \lambda_3^{-2} - 3), \quad (33)$$

with the nonlinear shear modulus

$$\mu_2 = b_1 + \frac{b_2}{a}. \quad (34)$$

In terms of the nonlinear shear modulus of the functions  $\mathcal{W}_1$  and  $\mathcal{W}_2$ , we have

$$\mu_2 = \tilde{\mu}(a) - \tilde{\mu}_1(a), \quad (35)$$

where  $\tilde{\mu}_1(a)$  is given by (30) and  $\tilde{\mu}(a) = \lim_{k \rightarrow 0} \mu$ , with  $\mu$  defined by (32). Therefore, the constants  $b_1$  and  $b_2$  can be found by calibrating (34) to the known values  $\tilde{\mu}_{\text{data}}(a) - \tilde{\mu}_1(a)$ , where  $\tilde{\mu}_{\text{data}}(a)$  are the values of the nonlinear shear modulus at small shear strain identified from the experimental data as shown in Appendix B.

*Step 3.* The resulting hyperelastic model (31) then consists of the free energy function  $\mathcal{W}_1$  and the correction function  $\mathcal{W}_2$ . The final model takes on the form

$$\begin{aligned} \mathcal{W}(\lambda_1, \lambda_2, \lambda_3) &= \frac{c_0}{2\alpha} (\lambda_1^{2\alpha} + \lambda_2^{2\alpha} + \lambda_3^{2\alpha} - 3) \\ &+ \frac{\bar{c}_1}{2} (\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) + \frac{\bar{c}_2}{2} (\lambda_1^{-2} + \lambda_2^{-2} + \lambda_3^{-2} - 3), \end{aligned} \quad (36)$$

in terms of four global parameters. The corresponding nonlinear shear modulus (11), the nonlinear shear modulus under small shear strain (15), and their linear elastic limit (16) are, respectively,

$$\mu(a, k) = c_0 \frac{\lambda_1^{2\alpha} - \lambda_2^{2\alpha}}{\lambda_1^2 - \lambda_2^2} + \bar{c}_1 + \frac{\bar{c}_2}{a}, \quad (37)$$

$$\tilde{\mu}(a) = \lim_{k \rightarrow 0} \mu(a, k) = c_0 \frac{a^{1-\alpha} (1 - a^{3\alpha})}{1 - a^3} + \bar{c}_1 + \frac{\bar{c}_2}{a}, \quad (38)$$

$$\mu_0 = \lim_{a \rightarrow 1} \tilde{\mu}(a) = c_0 \alpha + \bar{c}_1 + \bar{c}_2. \quad (39)$$

### 5.1. Model calibration

Next, we calibrate the model (36) to the human brain experiments (see Appendix A). At Step 1, the only experimental measurement we need to calibrate the model is the shear stress under simple shear superposed on a chosen axial stretch (see Appendix B). At Step 2, we require the nonlinear shear modulus under small shear superposed on varying compression or tension deformations. We then compare the predicted results for the shear stress and nonlinear shear modulus with experimental data for simple shear superposed on different axial deformations.

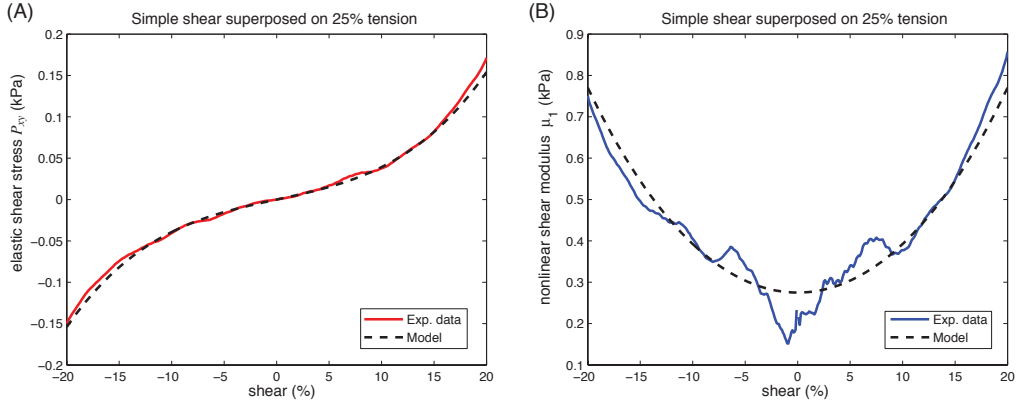

Figure 5: Constitutive behavior of strain-energy function  $\mathcal{W}_1$  under simple shear superposed on 25% axial tension, in Step 1: (A) Shear stress  $P_{xy}$  versus shear strain, experiment and model with parameters  $c_0 = 0.0653$  kPa,  $\alpha = 7.1813$ ,  $c_1 = -0.2302$  kPa, and  $c_2 = -1.9842$  kPa, and (B) nonlinear shear modulus  $\mu_1$  versus shear strain, experiment and model.

*Step 1.* (constitutive model initial calibration) First, we consider the experimental data for simple shear, up to 20%, superposed on 25% tension. Note that, in Figure 2, the nonlinear shear modulus at 25% tension is almost equal to that under simple shear. In Figure 5A, we calibrate the shear stress for the model  $\mathcal{W}_1$  in (28) to these data and obtain  $c_0 = 0.0653$  kPa,  $\alpha = 7.1813$ ,  $c_1 = -0.2302$  kPa, and  $c_2 = -1.9842$  kPa. In Figure 5B, the associated nonlinear shear modulus  $\mu_1$  of equation (29) is compared to the nonlinear shear modulus computed from the experimental data.

*Step 2.* (calibration correction) Second, from each experimental data set for the shear stress at different axial deformations, up to 25% compression or tension (in 5% increments), we evaluate the function (28) and its nonlinear shear modulus (30) and identify the nonlinear shear modulus values  $\tilde{\mu}_{\text{data}}(a)$  at small shear as explained

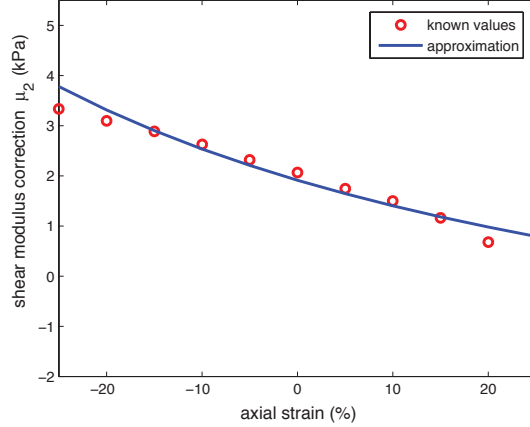

Figure 6: Constitutive behavior of strain-energy function  $\mathcal{W}_2$  in Step 2: Nonlinear shear modulus correction  $\mu_2$  versus compression or tension, experiment and model with parameters  $b_1 = -3.5899$  kPa and  $b_2 = 5.5218$  kPa.

in Appendix B. We then calibrate the nonlinear shear modulus correction  $\mu_2$  of equation (34) to the known values  $\tilde{\mu}_{\text{data}}(a) - \tilde{\mu}_1(a)$ , where  $\tilde{\mu}_1(a)$  is given by equation (30), and obtain  $b_1 = -3.5899$  kPa and  $b_2 = 5.5218$  kPa, as shown in Figure 6.

*Step 3. (constitutive model)* The final hyperelastic model is then given by the strain-energy function  $\mathcal{W} = \mathcal{W}_1 + \mathcal{W}_2$  of equation (36), i.e., the sum of the two models, with parameter values of  $c_0 = 0.0653$  kPa,  $\alpha = 7.1813$ ,  $\bar{c}_1 = c_1 + b_1 = -3.8201$  kPa, and  $\bar{c}_2 = c_2 + b_2 = 3.5376$  kPa. According to equation (39), the proposed model predicts a linear shear modulus of  $\mu_0 = c_0\alpha + \bar{c}_1 + \bar{c}_2 = 0.1864$  kPa, which corresponds to a Young's modulus of  $E_0 = 3\mu_0 = 0.5593$  kPa. This estimate for the shear modulus is lower than the one obtained in Appendix B.

Table 2 summarizes the three steps, with the corresponding strain-energy functions, model parameters, calibrated values, and units. Figure 7 compares the predicted shear stress  $P_{xy}$  and nonlinear shear modulus  $\mu$  with the experimental data for simple shear, up to 20% shear strain, superposed on up to 15% compression or tension (in 5% increments), and shows the relative errors. At large shear strains, close to 20%, the relative errors in Figure 7C are comparable with those in Figure 4C.

**Remark 2.** *Note that the overall model constructed here contains three terms with four parameters  $c_0 = 0.0653$  kPa,  $\alpha = 7.1813$ ,  $\bar{c}_1 = -3.8201$ ,  $\bar{c}_2 = 3.5376$ , i.e., only four parameters are needed for the finite element implementation of this model.*

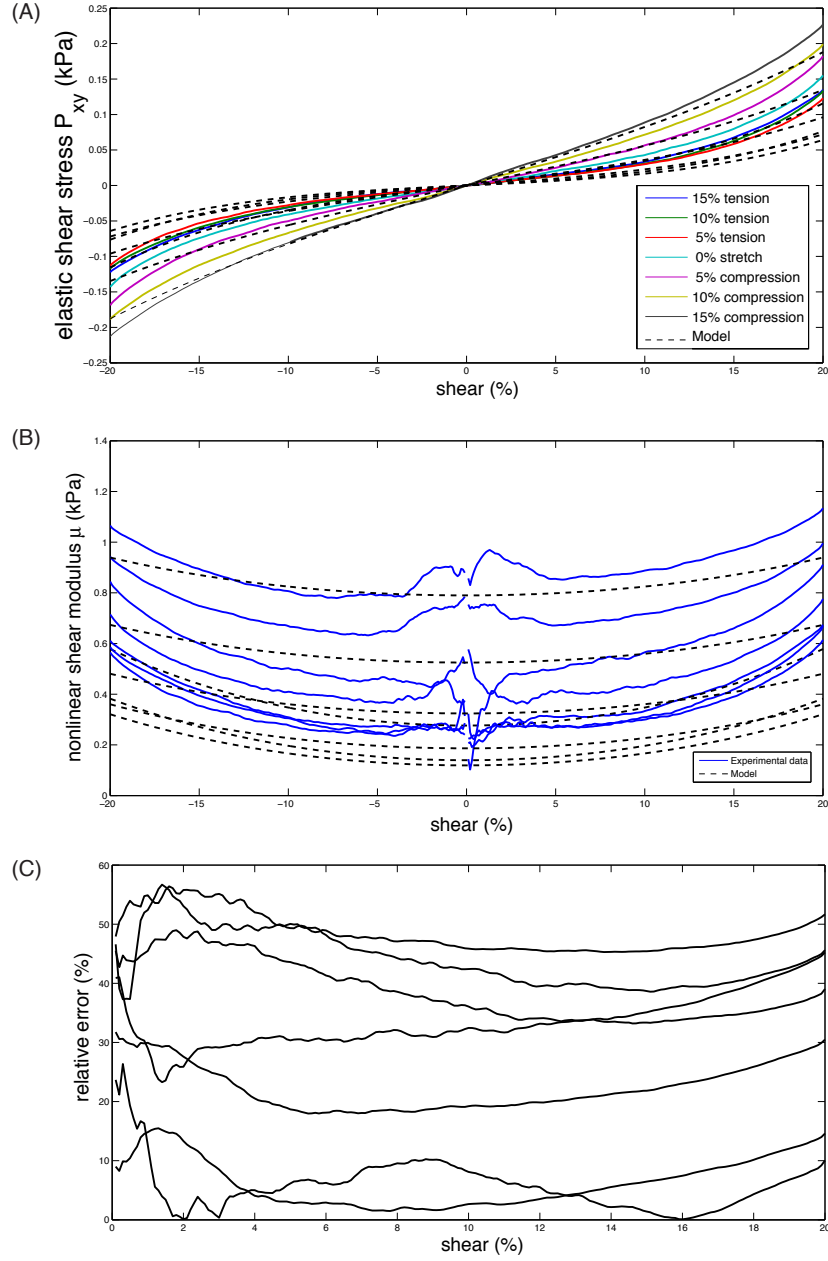

Figure 7: Constitutive behavior of strain-energy function  $\mathcal{W}$  with  $c_0 = 0.0653$  kPa,  $\alpha = 7.1813$ ,  $\bar{c}_1 = -3.8201$  kPa, and  $\bar{c}_2 = 3.5376$  kPa under simple shear superposed on different levels of axial tension or compression: (A) Shear stress  $P_{xy}$  versus shear strain, experiment and model, (B) nonlinear shear modulus  $\mu$  versus axial strain, experiment and model, and (C) associated relative error for the shear stress  $P_{xy}$ . The corresponding linear shear modulus is  $\mu_0 = 0.1864$  kPa.

Table 2: Strain-energy functions with related model parameters and calibrated values (and units) for human brain tissues.

## 6. Discussion

Understanding the constitutive behavior of human brain tissue is critically important to study its mechanical function, to evaluate the stresses that cannot be measured in vivo, and to predict its response to physiological and pathological loading. In spite of extensive research, we only now begin to understand that brain tissue belongs to a special class of soft tissues with unique and distinct constitutive properties. We typically associate soft tissues with a constitutive behavior that is primarily driven by the microstructure of their extracellular matrix with load bearing fibers of collagen and elastin. There is a general agreement to model this type of behavior with a strain-energy function supplemented by a strain-stiffening term that acts along the fiber direction. Probably the most prominent representative of this class of models is the Holzapfel-Gasser-Ogden model [16], which is widely used to model various soft tissues including arteries, heart valve, cardiac muscle, ocular tissue. While earlier attempts have simply adapted this model to simulate brain tissue [6], recent studies suggest that brain tissues behave inherently differently (see Appendix B). In particular, when brain tissue is subject to large strains, the shear modulus increases significantly under axial compression, but not under tension.

Experimental studies of human brain tissue have found that, in general, its behavior can reasonably be approximated by an Ogden-type model for nonlinear, in-

compressible, isotropic, rubber-like materials. Ogden models [32] are widely used and are appealing for many reasons, not least because they are readily available in many commercial software packages. In fact, the Ogden model outperforms many other commonly used models including the Neo-Hookean, Mooney-Rivlin, Fung, and Gent models when modeling human [4] and murine [23] brain tissue and fat under multiaxial loading. Our recent studies further reveal that, under combined finite shear and axial deformation, human brain tissue displays a pronounced tension-compression asymmetry, which manifests through a significant increase in shear stress with increasing axial compression compared to a moderate increase with increasing axial tension [4]. Similarly, in murine brain tissue under small shear, the nonlinear shear modulus increases with increasing axial compression but remains almost constant with increasing axial tension [23, 35]. By neglecting time-dependent material effects, such as viscoelasticity [43] or poroelasticity [12], and focusing exclusively on the quasi-time-independent elastic behavior, in [4], it is shown that, at fixed axial stretch, the one-term Ogden model performs well and captures accurately the variation of stress with respect to large shear. However, as axial stretch is varied, the two parameters change considerably. Hence, either a different model or a different calibration strategy is required under multiaxial loading. The experimental data shows that, for a given shear superposed on varying levels of tension and compression, the changes in the nonlinear shear modulus under large shear are qualitatively similar to those under small shear. Furthermore, in view of the many typical difficulties which arise from the numerical least-squares approximation of large experimental data sets, such as non-uniqueness of approximate feasible solution and strong dependency of the optimal solutions on initialization [34], our key observations about the particular behavior of the nonlinear shear modulus are essential in finding suitable model solutions.

Our first model consists of one Ogden-term with two parameters which are derived by a different calibration strategy than the one tested in [4]. Specifically, to find the two model parameters, we first identify reliable data for the nonlinear shear modulus under small shear deformations from our experimental measurements, then calibrate to these values the nonlinear shear modulus of the hyperelastic model under small shear superposed on varying axial tension or compression. We emphasize here that the preliminary step whereby we identify reliable data for the small shear range is only required because the available data are particularly noisy in that range. When reliable experimental data are provided directly, this preliminary step is not needed. In the linear elastic limit, the model parameters define a linear shear modulus of  $\mu_0 = 0.3779$  kPa, and, under the assumption of incompressibility, a Young's modulus of  $E_0 = 1.1338$  kPa. The results predicted by this model are in very good agreement

with all the given experimental data for simple shear superposed on different level of axial tension or compression simultaneously, especially in the small shear regime and in the linear elastic limit. However, under large shear deformations, the results are less accurate, since, as suggested by the experimental data, when compression increases, the nonlinear elastic modulus increases slower under larger shear, but when tension increases, the rate of increase in this modulus remains virtually the same for different levels of shear.

We also construct a three-term (four-parameter) Ogden-type model by systematically exploiting key findings from the available experimental data. Specifically, the multiaxial loading tests reveal that (i) the elastic response of brain tissue under varying shear superposed on different levels of tension and compression is qualitatively similar to the response under simple shear, and (ii) for a given shear superposed on varying levels of tension and compression, the elastic behavior under large shear is consistent with that under small shear. To capture these unique characteristics, we devise a three-step approach. First, we define a strain-energy function  $\mathcal{W}_1$  and introduce its nonlinear shear modulus  $\mu_1$ , which is a function of the deformation and represents the ratio between the shear stress and the shear. We calibrate the model parameters from the experimental data at finite deformation. Second, we correct the model by a second strain-energy function  $\mathcal{W}_2$  of Mooney-Rivlin-type with the nonlinear shear modulus  $\mu_2$  and calibrate the model parameters at the small shear strain limit. Third, we add both models to obtain the overall strain-energy function  $\mathcal{W} = \mathcal{W}_1 + \mathcal{W}_2$ . To formalize the procedure by which we identify our parameters, we use experimental measurements for the shear stress under simple shear superposed on a chosen axial stretch and for the shear modulus under small shear superposed on varying axial tension or compression. In the linear limit, these parameters define a linear shear modulus of  $\mu_0 = 0.1864$  kPa, and, under the assumption of incompressibility, a Young's modulus of  $E_0 = 0.5593$  kPa. With this parametrization, our model is capable of predicting the elastic behavior of human brain tissue under combined multiaxial loading.

Our proposed models are the only hyperelastic models to date calibrated simultaneously to experimental data for brain tissue under finite simple shear superposed on varying axial tension or compression. With the advantage of a robust and systematic parameter identification, the hyperelastic models proposed here may be generalized to other soft, lipid-rich biological tissues with similar constitutive features, including liver or adipose tissue. Critically, our modeling techniques highlight the central role played by the nonlinear shear modulus to explain tissue behavior in large deformations.

## Appendix A. Biomechanical testing

To characterize the mechanical response of human brain tissue under multiaxial loading, we extracted a total of four specimens of  $5 \times 5 \times 5\text{mm}^3$  from the corona radiata, the outer white matter, of three human cadavers obtained during autopsy from the local health authorities with a post mortem interval of less than 24 hours. Directly after autopsy, we cut one exemplary fresh tissue slice of each human brain for biomechanical testing and comparison. The study was approved by the Ethics Commission of the Medical University of Graz, Austria, with the approval number 25-420 ex 12/13. We kept the tissue refrigerated at  $3^\circ\text{C}$  and humidified with phosphate-buffered saline solution at all times to minimize tissue degradation. We tested all samples within 48 hours after subject acquisition. This resulted in a total post-mortem interval between death and the end of biomechanical testing of less than 60 hours. Note that the post-mortem time of up to 60 hours after death could potentially affect brain tissue properties. While studies on porcine brain tissue revealed a slight increase in tissue stiffness beginning 6 hours post-mortem [13], other experiments on bovine brain tissue showed no change in tissue stiffness between 2 hours and 5 days post mortem [3]. Within the time window between the first and last sample tested, we could not observe a notable change in tissue stiffness. We mounted each specimen onto the custom-designed triaxial testing device [45] to apply combined shear and compression or tension loadings. The system operates with a stroke resolution of  $0.04\ \mu\text{m}$  in the  $y$ -direction and with a stroke resolution of  $0.25\ \mu\text{m}$  in the  $x$ - and  $z$ -directions. We achieved motor control and data acquisition using the software testXpert II Version 3.2 (Zwick/Roell GmbH & Co. KG, Ulm, Germany) on a Windows-based personal computer. We conducted all tests at room temperature and chose quasi-static loading conditions with a speed of  $2\text{mm}/\text{min}$ . We first increased the compressive strain from 0% to 25% in increments of 5%, and subsequently the tensile strain from 5% to 25%, also in increments of 5%, by moving the upper platform in the  $y$ -direction. This resulted in axial stretches of  $a = (L_y + \Delta y)/L_y$  with a  $y$ -displacement  $\Delta y$  and a specimen height  $L_y$ . At each axial stretch level, we applied a sinusoidal simple shear up to a shear strain  $\gamma = ka = 0.2$  in the  $x$ - and  $z$ -directions, where the shear strain  $\gamma$  specifies the relative in-plane displacement of two parallel layers in the material body divided by their separation distance  $L_y$ . During shear loading, the lower platform moved relative to the fixed upper platform using a biaxial translation stage with the maximum displacements  $\Delta x = \Delta z = 0.2L_y$ . We applied three cycles of shear per stretch level and direction, where two cycles served as preconditioning steps and the third cycle was used for data analysis. We recorded the forces with a three-axe force-sensor (K3D40, ME-Measuring Equipment, Henningsdorf, Germany) and calculated the shear stresses  $P_{xy} = f/A$  and  $P_{yz} = f/A$  as

the shear force  $f$ , the force recorded in the direction of shear, divided by the shear area  $A = L_x L_z$  with the specimen length  $L_x$  and specimen width  $L_z$ . The “elastic” responses which we use for calibrating the hyperelastic constitutive model parameters were obtained as the average between the loading and unloading responses. For further discussions on the effects of post-mortem time and sample preparation, as well as on the limitations of in vitro testing and the methods used to extract elastic properties, we refer to [4].

## Appendix B. Preliminary approximation of experimental data

Given all the data sets for simple shear, up to 20%, combined with different compression or tension loading, up to 25% tension or compression (in 5% increments), we can calibrate the model  $\mathcal{W}_{\text{og}}$  defined by (17) for each prescribed stretch  $a$ , as in [4]. Figures B.8-B.9 show the constitutive behavior of the strain-energy function  $\mathcal{W}_{\text{og}}$  of equation (17) in terms of the shear stress  $P_{xy}$  versus shear strain, the nonlinear shear modulus  $\mu = P_{xy}/ka$ , and the relative error  $|P_{xy}^{\text{model}} - P_{xy}^{\text{data}}|/|P_{xy}^{\text{data}}|$ , where  $P_{xy}^{\text{model}}$  and  $P_{xy}^{\text{data}}$  represent the predicted and measured values of the shear stress, respectively, and  $|\cdot|$  denotes the absolute value. These figures also suggest that some of the collected data are inaccurate, as discontinuities and noise appear in the nonlinear shear modulus at less than 5% shear strain. Note that, since the discontinuities and the noise are in the gradient, they are not captured by the plots of the measured shear stress. Nevertheless, we can still calibrate the function  $\mathcal{W}_{\text{og}}$  to the correct experimental data, which leads to a very accurate approximation at over 5% shear, and consider the values of the shear stress and nonlinear shear modulus identified by the calibrated model as reliable predictions of the elastic behavior in both the small and the large shear regime. In particular, for each axial stretch  $a$ , the nonlinear shear modulus under small shear  $\tilde{\mu}(a)$  is given by (20), which for the purpose of this study we refer to as  $\tilde{\mu}_{\text{data}}(a)$ .

In the linear elastic limit, the shear modulus (21) identified for the model calibrated to the simple shear data, i.e.,  $\mathcal{W}_{\text{og}}$  with parameters  $c_0 = -0.0297$  kPa and  $\alpha = -11.3757$ , is equal to  $\mu_0 = c_0\alpha = 0.3379$  kPa. However, if we consider the strain energy function  $\mathcal{W}_{\text{og}}$  calibrated to the experimental data for simple shear and apply axial tension or compression followed by simple shear to this model, we find that the approximation of the experimental data corresponding to simple shear superposed on axial compression becomes less and less accurate as compression increases, even though the approximation of the data for simple shear superposed on axial tension is reasonable (see Figure B.10).

In [22], a hyperelastic model calibrated to experimental data for porcine brain tissue subject to simple shear was proposed, whereby the shear stress increases lin-

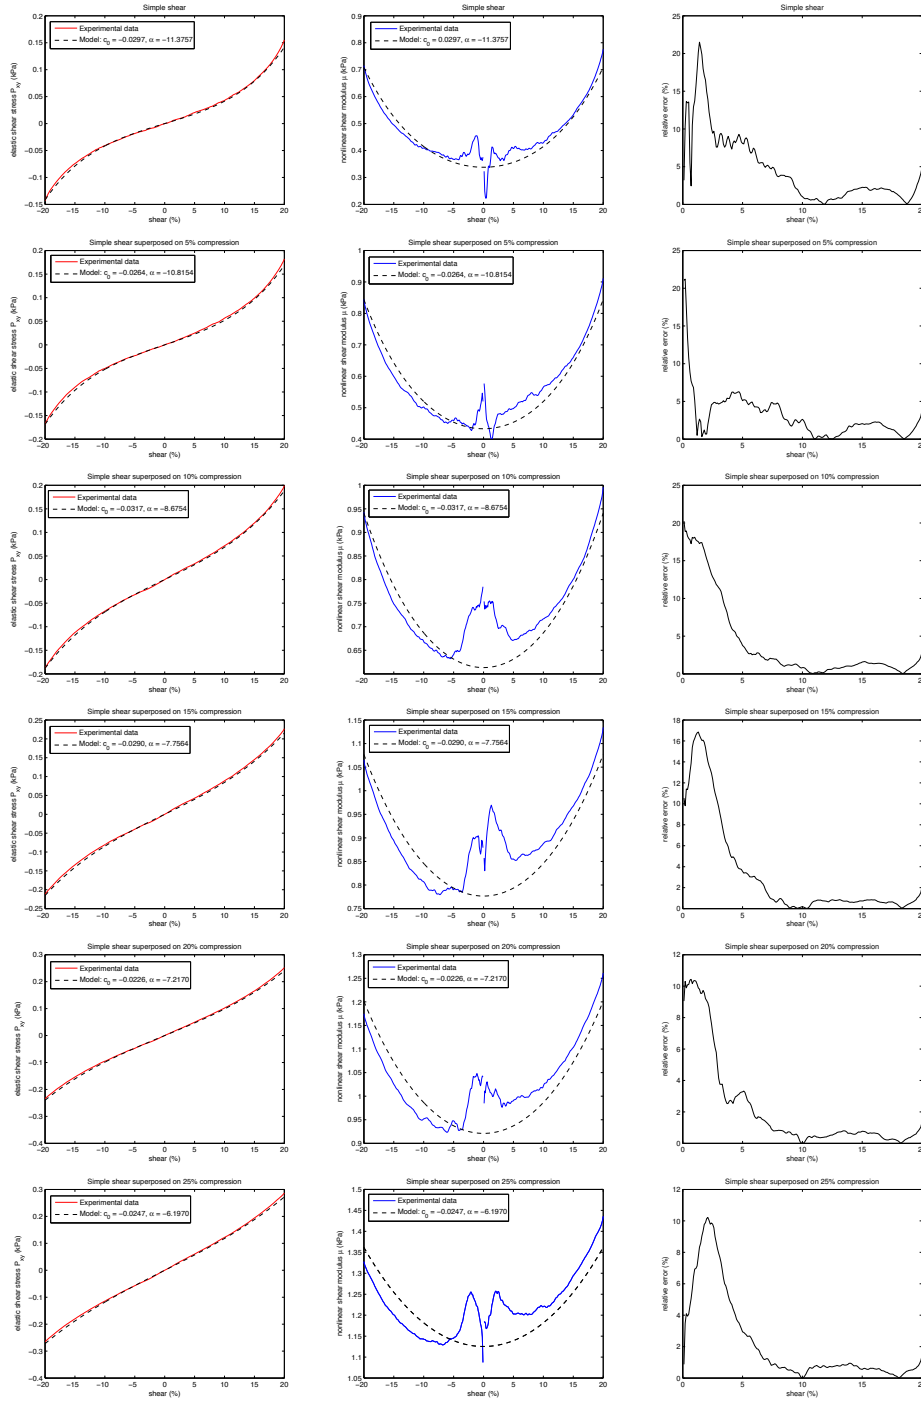

Figure B.8: Shear stress  $P_{xy}$  and nonlinear shear modulus  $\mu$  versus shear strain predicted by the hyperelastic model  $W_{og} = c_0(a) \left( \lambda_1^{2\alpha(a)} + \lambda_2^{2\alpha(a)} + \lambda_3^{2\alpha(a)} - 3 \right) / (2\alpha(a))$  with (black dashed curve) compared to individual data sets (colored continuous line) for simple shear and for simple shear superposed on different axial deformations, and relative errors for the shear stress  $P_{xy}$ , for simple shear and simple shear superposed on different axial compressions.

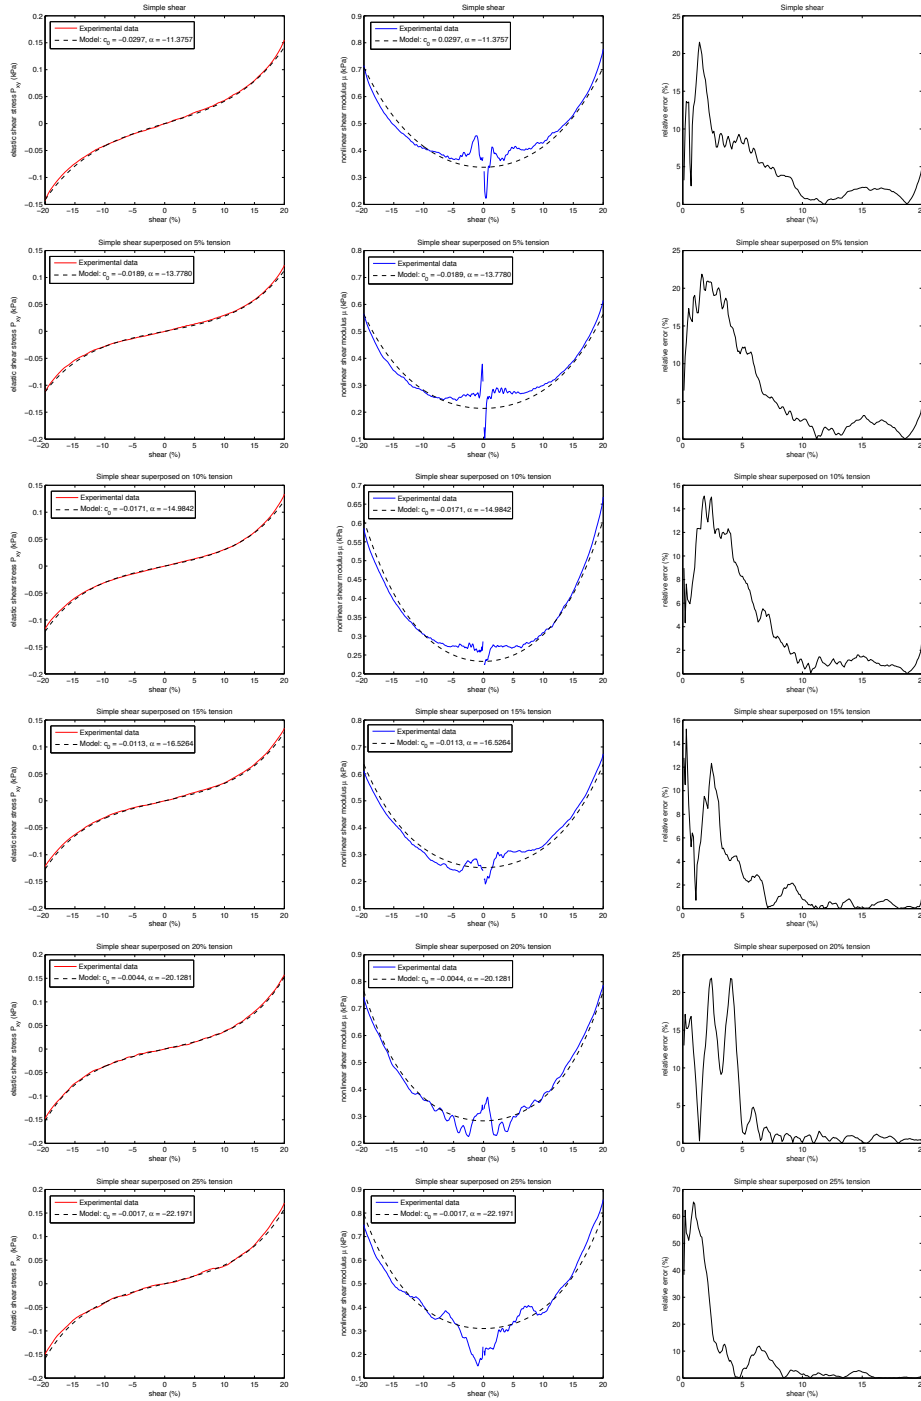

Figure B.9: Shear stress  $P_{xy}$  and nonlinear shear modulus  $\mu$  versus shear strain predicted by the hyperelastic model  $W_{og} = c_0(a) \left( \lambda_1^{2\alpha(a)} + \lambda_2^{2\alpha(a)} + \lambda_3^{2\alpha(a)} - 3 \right) / (2\alpha(a))$  with (black dashed line) compared to individual data sets (colored continuous curve) for simple shear and for simple shear superposed on different axial deformations, and relative errors for the shear stress  $P_{xy}$ , for simple shear and for simple shear superposed on different axial tensions.

Table B.3: Publications where experimental results for brain tissue under shear were reported, with the conditions of measurement and number of test data available for model calibration specified.

tissue	temperature	deformation	strain rate	strain range	data	reference

Figure B.10: Constitutive behavior of strain-energy function  $\mathcal{W}_{\text{og}} = c_0(a) \left( \lambda_1^{2\alpha(a)} + \lambda_2^{2\alpha(a)} + \lambda_3^{2\alpha(a)} - 3 \right) / (2\alpha(a))$  with parameters  $c_0 = -0.0297$  kPa and  $\alpha = -11.3758$  under simple shear superposed on up to 15% axial tension or compression: (A) nonlinear shear modulus  $\mu$  versus axial strain, given data and model, and (B) associated relative error for the shear stress  $P_{xy}$ .

early with respect to the shear parameter  $0 \leq K \leq 1$ , as also shown experimentally by [40]. A careful inspection of the experimental data in [22, 40] suggests that there are 3 to 5 non-zero test data supplied for simple shear with shear parameter  $0 \leq K \leq 0.2$ , corresponding to 0% to 20% shear strain. Our experimental tests for human brain tissue provide 201 data values for simple shear from 0% to 20% shear strain (see top-left-hand plot in Figure B.8, or equivalently top left-hand plot in Figure B.9), and similarly, 401 data for every simple shear deformation superposed on up to 25% tension or compression, in 5% increments, i.e.,  $401 \times 11$  data values in total. More importantly, while the tests in [22, 40] were carried out without pre-conditioning and at high strain rates (30/s or higher, requiring velocities of over 120mm/s), the experimental measurements for our study were taken under quasi-static loading (with velocity of 2mm/min), and averaged between the loading and unloading paths (see Appendix A). For human brain tissue, in [44], a linear behaviour compatible with a Neo-Hookean model was found under small torsion, up to 3.5% strain. The linear behaviour of both porcine and human brain tissue in shear was also observed in [30, 31], where Ogden models were proposed for large deformations. Softening in shear was noted by [19, 20, 35, 37]. By contrast, stiffening in shear was reported in [4, 8, 11]. Furthermore, in [8], the discrepancies observed in the mechanical properties of brain tissue in other studies were shown to be related to the strain conditioning effect, consisting in non-recoverable changes in the mate-

rial properties under finite strains, which also make the mechanical responses of the tissue almost isotropic.

Table B.3 summarizes the above mentioned publications, where experimental results under shear or combined stretch and shear deformations of brain tissues were reported. From this table, we see that there are wide variations in the conditions of measurement, particularly those reported by different authors. Besides, the data which many authors provide to calibrate hyperelastic models are rather sparse, and the table clearly demonstrates that the data set which we analyse here is the most extensive and the only one for brain tissue in finite multiaxial loading. This precludes conclusive quantitative comparisons between independent results [5], and makes mathematical modeling of this tissue extremely challenging. Nevertheless, it can reasonably be inferred that, when brain tissue is subject to large strains, the shear stress increases strongly under axial compression, regardless of the stress-strain response due to shear deformation alone [4, 35].

### Appendix C. Three-term (three-parameter) constitutive model

In this appendix, at Step 2 in Section 4, we consider the three-term (three-parameter) Ogden model

$$\begin{aligned} \mathcal{W}_3(\lambda_1, \lambda_2, \lambda_3) &= \frac{c_1}{2} (\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) \\ &+ \frac{c_2}{2} (\lambda_1^{-2} + \lambda_2^{-2} + \lambda_3^{-2} - 3) \\ &+ \frac{c_3}{4} (\lambda_1^4 + \lambda_2^4 + \lambda_3^4 - 3), \end{aligned} \quad (\text{C.1})$$

with the constant parameters  $c_i$ ,  $i = 1, 2, 3$ , instead of the one-term (two-parameter) hyperelastic model (22). For the three-term model, the nonlinear shear modulus (11), the nonlinear shear modulus under small shear strain (15), and their linear elastic limit (16) take on the following explicit forms

$$\mu(a, k) = c_1 + \frac{c_2}{a} + c_3 (\lambda_1^2 + \lambda_2^2), \quad (\text{C.2})$$

$$\tilde{\mu}(a) = \lim_{k \rightarrow 0} \mu(a, k) = c_1 + \frac{c_2}{a} + c_3 \frac{1 + a^3}{a}, \quad (\text{C.3})$$

$$\tilde{\mu}_0 = \lim_{a \rightarrow 1} \tilde{\mu}(a) = c_1 + c_2 + 2c_3. \quad (\text{C.4})$$

To derive the model parameters, we calibrate the nonlinear shear modulus  $\tilde{\mu}(a)$  of equation (C.3) to the known values  $\tilde{\mu}_{data}(a)$  identified at the preliminary Step 1 in

Section 4 (see also Appendix B), for small shear superposed on up to 25% tension or compression (in 5% increments), and obtain  $c_1 = -5.5090$  kPa,  $c_2 = 2.9269$  kPa, and  $c_3 = 1.4653$  kPa. This calibration is illustrated in Figure C.11 together with the associated relative error  $|P_{xy}^{\text{model}} - P_{xy}^{\text{data}}|/|P_{xy}^{\text{data}}|$ . A quick comparison with the relative errors shown in Figure 3C suggests that this three parameter model (C.1) offers a slightly closer match to the given data for small shear superposed on varying tension or compression than the two parameter model (22).

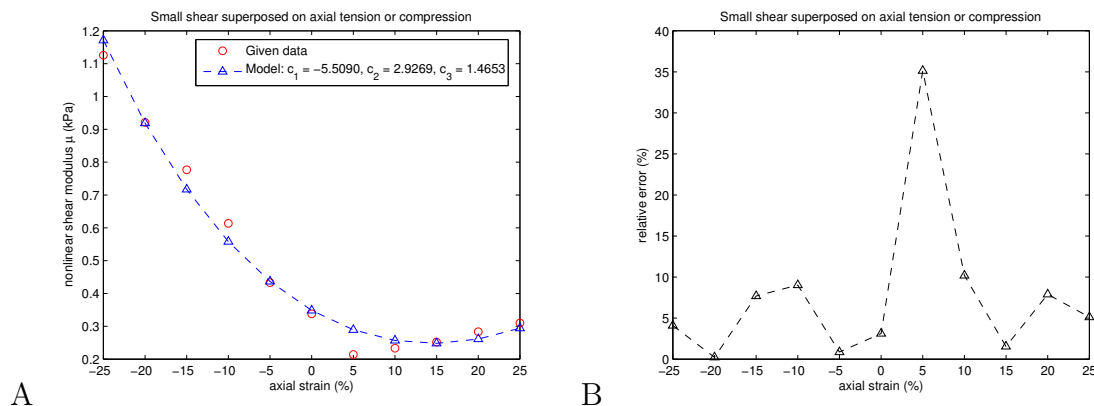

Figure C.11: Constitutive behavior of strain-energy function  $\mathcal{W}_3 = c_1 (\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) / 2 + c_2 (\lambda_1^{-2} + \lambda_2^{-2} + \lambda_3^{-2} - 3) / 2 + c_3 (\lambda_1^4 + \lambda_2^4 + \lambda_3^4 - 3) / 4$  with parameters  $c_1 = -5.5090$  kPa,  $c_2 = 2.9269$  kPa, and  $c_3 = 1.4653$  kPa under small shear superposed on axial tension or compression: (A) nonlinear shear modulus  $\tilde{\mu}$  versus axial strain, given data and model, and (B) associated relative error for the shear stress  $P_{xy}$ .

This model predicts a linear shear modulus (C.4) of  $\mu_0 = 0.3485$  kPa and a Young's modulus of  $E_0 = 3\mu_0 = 1.0455$  kPa. Thus the three parameter model (C.1) produces a slightly more accurate approximation to the linear shear modulus  $\mu_0 = 0.3379$  kPa identified at Step 1 (see Appendix B) than the two parameter model (22).

Table C.4 summarizes the strain-energy function for this hyperelastic model, its constant parameters, their calibrated values, and units. Figure C.12 summarizes the predicted shear stress  $P_{xy}$  and nonlinear shear modulus  $\mu$  compared to the experimental data sets for simple shear, up to 20% shear strain, superposed on up to 25% compression or tension (in 5% increments), and the relative errors. A comparison with Figure 4 further suggests that, in large shear also, the results predicted by the three-parameter model (C.1) are closer to the given data than those predicted by the two parameter model (22). However, the decrease in the relative errors shown in

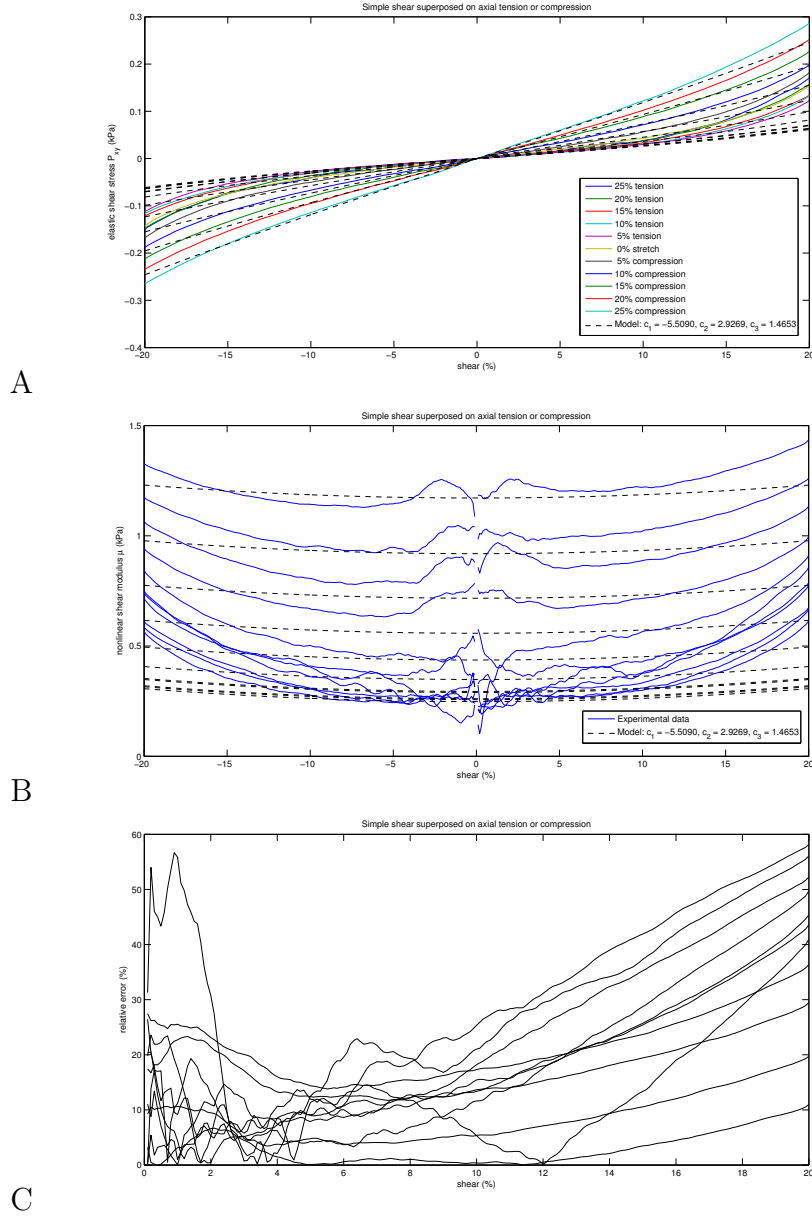

Figure C.12: Constitutive behavior of strain-energy function  $\mathcal{W}_3 = c_1 (\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) / 2 + c_2 (\lambda_1^{-2} + \lambda_2^{-2} + \lambda_3^{-2} - 3) / 2 + c_3 (\lambda_1^4 + \lambda_2^4 + \lambda_3^4 - 3) / 4$  with parameters  $c_1 = -5.5090$  kPa,  $c_2 = 2.9269$  kPa, and  $c_3 = 1.4653$  kPa under simple shear superposed on different levels of axial tension or compression: (A) Shear stress  $P_{xy}$  versus shear strain, experiment and model, (B) nonlinear shear modulus  $\mu$  versus axial strain, experiment and model, and (C) associated relative error for the shear stress  $P_{xy}$ . The corresponding linear shear modulus is  $\mu_0 = 0.3438$  kPa.

Table C.4: Strain-energy function with related model parameters and calibrated values (and units) for human brain tissues.

strain energy	eq.	model	parameter	value	unit
$\mathcal{W}_3$	(C.1)	Ogden	$c_1$	-5.5090	kPa
			$c_2$	2.9269	kPa
			$c_3$	1.4653	kPa
linear elastic limit	(C.4)	-	$\mu_0$	0.3485	kPa

Figure C.12C compared to those in Figure 4C is limited, especially at more than 10% shear. This trend was also observed when the number of Ogden terms was further increased, even though the approximation under small shear superposed on varying axial stretch continued to improve, as discussed in [23] (results not shown).

### Acknowledgements

The support for L. Angela Mihai by the Engineering and Physical Sciences Research Council of Great Britain under research grant EP/M011992/1 is gratefully acknowledged. This work was supported also by the German National Science Foundation grant STE 544/50 to Silvia Budday, by the Humboldt Research Award and the National Institutes of Health grant U01 HL119578 to Ellen Kuhl, and by the Timoshenko Scholar Award to Alain Goriely.
